## INFORMATION TO USERS

This material was produced from a microfilm copy of the original document. While the most advanced technological means to photograph and reproduce this document have been used, the quality is heavily dependent upon the quality of the original submitted.

The following explanation of techniques is provided to help you understand markings or patterns which may appear on this reproduction.

1. The sign or "target" for pages apparently lacking from the document photographed is "Missing Page(s)". If it was possible to obtain the missing page(s) or section, they are spliced into the film along with adjacent pages. This may have necessitated cutting thru an image and duplicating adjacent pages to insure you complete continuity.
2. When an image on the film is obliterated with a large round black mark, it is an indication that the photographer suspected that the copy may have moved during exposure and thus cause a blurred image. You will find a good image of the page in the adjacent frame.
3. When a map, drawing or chart, etc., was part of the material being photographed the photographer followed a definite method in "sectioning" the material. It is customary to begin photoing at the upper left hand corner of a large sheet and to continue photoing from left to right in equal sections with a small overlap. If necessary, sectioning is continued again — beginning below the first row and continuing on until complete.
4. The majority of users indicate that the textual content is of greatest value, however, a somewhat higher quality reproduction could be made from "photographs" if essential to the understanding of the dissertation. Silver prints of "photographs" may be ordered at additional charge by writing the Order Department, giving the catalog number, title, author and specific pages you wish reproduced.
5. PLEASE NOTE: Some pages may have indistinct print. Filmed as received.

## CHAPTER I.

## STATEMENT OF THE PROBLEM

The financing of postsecondary education is undergoing rapid change. The student, who has always borne a large part of higher education costs in the form of foregone income, will be required in the future to pay a larger part of the direct costs also. This will be true especially for students from middle- and upper-income families, since much of the direct aid to students from all levels of government will be based on need. Such predictions are sufficiently widespread in the literature of higher education finance so as to require no documentation.

The impetus to the distribution of aid on the basis of need derives from the interaction of three dissimilar factors. First, equal access to postsecondary education has become an important goal of master planning at both the state and federal level. Second, broad agreement prevails that the family should provide as best it can for the postsecondary education of its dependents. Third, financial aid funds are and will continue to be scarce. These phenomena taken together mandate the distribution of aid funds according to need. Simultaneously, the measurement of need becomes a task of central importance.

Most postsecondary students who apply for financial aid are classified as dependent students. These students are to be distinguished from self-supporting students in that the financial circumstances of the student's family (parents or guardians) are relevant in assessing the need of dependent students, that is, students who are not self-supporting. Although alternative definitions of the dependent and the self-supporting

student exist, consensus definitions will probably emerge. The resulting definitions are likely to leave the majority of postsecondary students in the dependent category. Such students will continue to submit a parental (guardian) financial profile in order to qualify for aid. These profiles will be analyzed to ascertain the family's ability to contribute to the postsecondary education of the student. In a very real sense, the family will continue to be "taxed" for an educational contribution on the basis of ability to pay. This expected contribution will then be subtracted from the school's budget to determine need. Hence, the measurement of well-being and the implementation of principles of taxation will endure as major problems in need analysis.

An optimum need analysis model for computing the expected contribution of parents must be based necessarily on an appropriate measure of well-being and sound principles of taxation. Accordingly, horizontal and vertical equity are cited often as characteristics, indeed requirements, of a fair need analysis system. Briefly, horizontal equity suggests equal treatment of equals. Vertical equity, on the other hand, refers usually to systematically unequal treatment of unequals resulting in equal sacrifice. Both principles in unison require equal sacrifice of some sort for all families.

The achievement of equal sacrifice through taxation for an educational contribution presupposes the precise measurement of family well-being. Unacceptably large deviations from horizontal and vertical equity can result from inaccuracy in the assessment of well-being as well as from undesirable features of a practical system of taxation. Accordingly, the pursuit of equity in the distribution of aid funds should begin with

the choice and the refinement of an index of well-being which exhibits promise in measuring the family's ability to contribute to the post-secondary education of its dependents.

The choice of such an index requires great care. Two indices, both of which seem consistent with received theory, need not have the same implications for the perceived distribution of well-being among families. In general, two major differences could emerge. First, the rankings of families provided by each index could be identical, but the relative well-being of each family might be different. Second, the rankings themselves could differ significantly. Of course, if a change from one index to the other does not preserve the order of families, the well-being of each family relative to at least one family must change. In either case, a tax structure which succeeds in achieving horizontal and vertical equity in terms of one index will fail to do so for the other. The extended example that follows demonstrates these propositions.

Consider briefly the following data for five two-parent, one-child families for whom a measurement of well-being and a ranking is desired:

	<u>Income</u>	<u>Net Worth</u>	<u>Age of Parents</u>
A	\$8,000	\$30,000	46
B	8,250	25,000	49
C	8,500	20,000	52
D	8,750	15,000	55
E	9,000	10,000	58

Although the data above are hypothetical and have been constructed to dramatize the desired conclusion, one should keep in mind the fact

that each profile approximates the financial position of large numbers of families that do indeed apply for financial aid for their child.

Next consider the following four propositions concerning the construction of a simple index of well-being:

- (1) Current yearly income is the appropriate measure of the relative well-being among the families above.
- (2) Current yearly income and current net worth separately are the appropriate measure of the relative well-being among the families above.
- (3) Current yearly income and current net worth combined by converting net worth to an income flow and adding the result to income is the appropriate measure of the relative well-being among the families above.
- (4) Current and future yearly income and current net worth combined by computing the present value of expected lifetime earnings and adding the result to net worth is the appropriate measure of the relative well-being among the families above.

Using the hypothetical data presented in the table, it is possible to assign a dollar value to each of these alternative measures of well-being for each family and inspect the ranking and the distribution of well-being to which each measure gives rise.

If a current yearly income alone is used to measure well-being, the value of the index for each family is identical to the income figure in the table and the ranking and distribution which results is given by:

$$(1a) \quad \begin{array}{ccccc} A < B < C < D < E \\ .188 & .194 & .200 & .206 & .212 \end{array}$$

that is, A with .188 of the total well-being is worse off than B with .194, and so on. This notation will be used throughout the example and will include the symbol (=) when identical economic positions are to be identified.

On the other hand, if net worth is to be considered in the construction of the index of well-being, there are many procedures consistent with Propositions 2, 3, or 4 to construct such an index. For example, Proposition 2 calls for separate treatment of income and net worth. A two-dimensional index including the value of both income and net worth is consistent with this proposition. A problem arises, however, in assessing the absolute and relative welfare of each family in this case. In addition, ranking the families becomes difficult. If income is examined, the ranking and distribution (as before) which results is given by:

$$(2a) \quad \begin{array}{ccccc} A < B < C < D < E \\ .188 & .194 & .200 & .206 & .212 \end{array}$$

However, examination of net worth results in the ranking and distribution:

$$(2b) \quad \begin{array}{ccccc} A > B > C > D > E \\ .300 & .250 & .200 & .150 & .100 \end{array}$$

If both income and net worth are considered, it becomes impossible to rank the five hypothetical families. Similarly, the distribution of well-being is ambiguous. It should be noted at this point, that the proposition to consider income alone is really a special case under the proposition to consider income and net worth separately. Unlike the former, however, the latter does not allow unambiguous well-being comparisons.

If both income and net worth are to enter into the computation of well-being, some means of combining income and assets is needed, arbitrary or otherwise.

The third proposition describes in general terms a method of incorporating net worth in the well-being index. The conversion of net worth to an income flow might be achieved by multiplying the net worth of each family by the same conversion factor--for example, .05. When the resulting income flow is added to income, the index of well-being assumes a value of 9,500 for each family, and the following ranking and distribution results:

$$(3a) \quad \begin{array}{ccccc} A & = & B & = & C & = & D & = & E \\ .200 & .200 & .200 & .200 & .200 & .200 & .200 & .200 \end{array}$$

This computation is identical to the computation of an annuity of infinite duration given a discount rate of 5%. It is interesting to note that use of a discount rate of 6% results in the following values for the index of well-being:

A	9,800
B	9,750
C	9,700
D	9,650
E	9,600

providing the ranking and distribution

$$(3b) \quad \begin{array}{ccccc} A & > & B & > & C & > & D & > & E \\ .202 & .201 & .200 & .199 & .198 \end{array}$$

while use of a discount rate of 4% gives the following values:

A	9,200
B	9,250
C	9,300
D	9,350
E	9,400

and the ranking and distribution

$$(3c) \quad A < B < C < D < E$$

.198	.199	.200	.201	.202
------	------	------	------	------

Another procedure consistent with the third proposition is the simple addition of family income and net worth to derive measures of well-being. This procedure, of course, is identical to assuming liquidation of net worth at full value in the current period. The resulting values are:

A	38,000
B	33,250
C	28,500
D	23,750
E	19,000

and the ranking and distribution

$$(3d) \quad A > B > C > D > E$$

.267	.233	.200	.167	.133
------	------	------	------	------

One last procedure to convert net worth to an income flow involves use of the data on age of parents. Using a discount rate of 5% and annuitizing net worth over the expected lifetime of the father, results in the values

A	10,100
B	10,250
C	10,300
D	10,250
E	10,100

and the ranking and distribution

$$(3e) \quad A = E < B = D < C$$

.198	.198	.201	.201	.202
------	------	------	------	------

Finally, the fourth proposition suggests combining income and net worth by computing the present discounted value of expected lifetime earnings and adding the result to net worth. A procedure for accomplishing this will be explained in detail in the following chapter. For now, suffice it to say that when this procedure is used along with census data,

the following values emerge:

A	134,800
B	119,875
C	101,600
D	83,250
E	62,000

providing the ranking and distribution

$$(4a) \quad A > B > C > D > E \\ .269 \quad .239 \quad .203 \quad .166 \quad .124$$

This result depends also on the assumption that the males are Caucasian. By varying the race in the example, one could generate many different rankings and distributions.

The data below summarize the results.

<u>Proposition</u>	<u>Procedure</u>	<u>Ranking</u>	<u>A</u>	<u>B</u>	<u>C</u>	<u>D</u>	<u>E</u>
1	a	A<B<C<D<E	.188	.194	.200	.206	.212
2	a	A<B<C<D<E	.188	.194	.200	.206	.212
	b	A>B>C>D>E	.300	.250	.200	.150	.100
3	a	A=B=C=D=E	.200	.200	.200	.200	.200
	b	A>B>C>D>E	.202	.201	.200	.199	.198
	c	A<B<C<D<E	.198	.199	.200	.201	.202
	d	A>B>C>D>E	.267	.233	.200	.167	.133
	e	A=E<B=D<C	.198	.201	.202	.201	.198
4	a	A>B>C>D>E	.269	.239	.203	.166	.124

The data indicate that the four propositions give rise to many different rankings and distributions. Indeed, the third proposition alone results in four different rankings and five different distributions depending upon the procedure employed. This means, for example, that a tax of \$1,000 levied on each of the families, would achieve horizontal equity,

given Proposition 3 and Procedure a, but would fail to do so for all others. This conclusion is especially sobering when the reason for choosing the propositions in the example is revealed. Each proposition represents a competing view of the proper treatment of income and assets in need analysis. As such, each is a likely candidate to underpin need analysis systems in the future.

As the reader has probably surmised, the results in the example above depend on the nature of the hypothetical data used as well as on the techniques used to construct the measures of well-being. That is, the relationship among income, assets, and age of parents present in the hypothetical data has, in part, determined the various distributions. There is an important lesson to be learned from this. Analysis of the theoretical characteristics uncovers many arbitrary assumptions and value judgments inherent in each approach. It is important to investigate the effects of such features on the perceived distribution of well-being among a properly drawn sample of aid applicant families.

The purpose of the following chapters is to discuss the theoretical and practical implications of various measures of well-being consistent with these propositions. Chapter Two compares the propositions in light of received economic theory after modifying each proposition to include a simple family size correction. Chapter Three presents the design and results of an empirical examination of the perceived distribution of well-being consistent with the measures developed in Chapter Two, using financial and demographic data from 2,320 families. Finally, Chapter Four discusses the limitations of the analysis in the context of directions for future research.

## CHAPTER II.

## SOME ALTERNATIVE MEASURES OF WELL-BEING

As was suggested in Chapter One, the traditional approach to the equitable distribution of aid funds has two noteworthy characteristics. First, such distribution is viewed as a problem of taxation based on ability to pay. The tax involved is one that demands a contribution from parents to the financing of postsecondary education for their dependents. Second, the expenditure side of the budget is assumed to be given or determined by forces irrelevant to the determination of tax shares. Consequently, this approach ignores the possibility of identifying the benefits to recipients of postsecondary educational services or their families and allocating tax shares accordingly. In short, this approach emphasizes the distribution of the tax bill, in isolation, as a matter of equity and/or welfare economics. It is this approach, or more specifically, the first step in such an approach which is the focus of this study--an objective index of ability to pay or measure of well-being. The construction of such an index must precede not only the consideration of its relationship to utility; but also, the embodiment of any equal sacrifice principle in a specific tax schedule.

The purpose of this chapter is to analyze the advantages and disadvantages of three general frameworks for measuring the well-being of families of financial aid applicants. These frameworks entail measuring well-being from three different standpoints using different data and computational procedures. These general frameworks are:

- (1) current income adjusted for family size,

- (2) current income and current net assets combined adjusted for family size, and
- (3) current and future income and current net assets combined adjusted for family size.

The measures of well-being analyzed in this chapter are used in Chapter Three to construct Lorenz distributions for a group of 2,320 families. These distributions are then compared in terms of overall inequality and the treatment of specific subsets of the families.

The reader should bear in mind that the discussion which follows centers upon the appropriateness of alternative measures of well-being with regard to a specific subset of the population--the families of financial aid applicants. The point that is being addressed is the ability of such families to contribute to the financing of postsecondary education for their dependents. Consequently, the various measures which receive attention in this paper provide glimpses of perceived well-being either at a point in time or over a very short time span. In addition, certain practical considerations constrain the measure of well-being to be a relatively simple one. First, there is the need for the measure to appear both understandable and fair to those who provide scarce aid funds as well as to those who apply for and receive the funds. Second, there is the need for administrative convenience in allocating the funds. To the extent that these two factors limit the amount and type of data which a measure of well-being can draw upon, the choice of the measure is likewise constrained.

Obviously, the most serious difficulties are encountered in the collection of valid and reliable financial data from the families of financial aid applicants. The parents (guardians) realize, of course, that the information provided serves as input into a need analysis model which determines their expected contribution. Consequently, the temptation to underestimate their income and/or assets under such circumstances is powerful indeed. Methods to increase the validity and reliability of such data are not within the scope of this study. However, it is important to note that the desire to collect good data has led to a delimiting of the amount and type of data gathered. For instance, the data used to compute net assets for 2,320 families in Chapter Three consists of:

- (1) financial assets minus debts against such assets;
- (2) home, farm, and/or business equity; and
- (3) other assets including other real estate minus debts  
against such real estate and the value of trusts.

This type of data is typical of that which is required in all existing need analysis models. For instance, the information required from the family of a dependent student applying for a Basic Educational Opportunity Grant follows the outline above and adds only those net assets in the form of consumer durables and personal assets which are worth over \$500 each. Certainly, the inclusion of such assets and debts, in theory, would cause the aggregate net asset figure to more closely approximate what economists refer to as Net Worth (exclusive of human capital). It is difficult for this writer to believe that valid and reliable data on consumer durables can be collected without extensive surveillance procedures. Because of these difficulties the reader is asked to bear in mind

that the term net assets as used in this paper refers to a specific subset of nonhuman wealth which may or may not correlate highly with a more theoretically satisfying construct.

Given the specific purpose of the well-being measure and the desire for relative simplicity, there are certain basic theoretical characteristics which the measure must exhibit. Specifically, the measure must be a function which assigns a dollar value to the well-being of every conceivable family in the subset, thereby providing a cardinal ranking of families characterized by preference and indifference. That is, the function when evaluated for two families A and B, must reveal A to be better off than B, B to be better off than A, or A and B to equal in well-being. Furthermore, if Family C is revealed to be better off than A, and A to be better off than B, then C must be revealed to be better off than B. The same must hold true for identical positions of well-being also.

Each of the measures considered in this chapter fulfills the practical and theoretical requirements given above. Indeed, it is these requirements which cause exclusion of one of the measures in the example in Chapter I--the treatment of current income and net assets separately. Such a measure does not provide a ranking with the desired characteristics.

It should also be pointed out again that this study employs for convenience a simple per capita family size adjustment. This, of course, ignores an important factor which seems relevant in the construction of such an adjustment. Specifically, a simple per capita adjustment ignores the relationship between family size and age distribution and the amount of total family satisfaction which can be wrung from a given dollar measure of well-being. Suppose, for example, that the dollar cost of

providing a given level of satisfaction increased with family size but at a decreasing rate. In such a case, a per capita adjustment of family income would cause the measure of well-being to underestimate the well-being of larger families. Such underestimation of well-being could be further strengthened by the failure of the well-being measure to include any satisfaction derived from family size or age distribution.

The first measure of well-being to be considered in this study is current income per capita. The overriding advantages of employing income adjusted for family size as the measure of well-being are understandability and administrative convenience. Everyone is familiar with the concept of yearly income--or income averaged over a definite time period--and self-reported income data can be verified easily through the Federal Income Tax system--cheating notwithstanding.

A more subtle advantage of using current income adjusted for family size occurs if one makes the value judgment that the family's contribution to the financing of postsecondary education for its dependents should be financed from current income over the time span when those dependents are in postsecondary education. Although the allocation of current income to the finance of postsecondary education must affect a family's potential net worth position, one could minimize such effects by constructing a tax on current income adjusted for family size so as to allow a family to at least maintain its standard of living and net worth position over the appropriate time period. Since income as reported on the Federal Income Tax in the most recent complete tax year is a good predictor of current income as eventually reported, measuring well-being using current income adjusted for family size may seem attractive.

The use of current income adjusted for family size is clearly more palatable when the income data used includes all accretions to and diminutions of nonhuman wealth. In this case, income would equal current consumption plus increase in net worth. This is not so, however, with total income as reported for Federal Income Tax purposes. Such income figures do not include unrealized accretions to and diminutions of wealth. For instance, an increase in the value of an asset from \$100 to \$200 does not affect this concept of total income. Similarly, if a consumer durable has depreciated in the current period, total income for tax purposes is not affected. It is extremely unlikely that, for a given family and a given period, accretions and diminutions would cancel out. Furthermore, federal and state taxation of realized income is, in part, a function of the source from which it accrues. Loopholes, of course, to the extent that they favor certain groups with regard to asset accumulation, make the ignoring of current asset holdings less acceptable. It should be pointed out that the considerations above refer to unfortunate characteristics of the data used to measure current income and the system under which it is taxed, rather than to an ideal measure of current income and an ideal system of taxation. Both of the objections above are overcome, in part, when current asset holdings are included with current income in the measure of well-being.

It is easy to use Musgrave's (5) outline of characteristics of the accretion concept of income to discover more disadvantages of using current income on the Federal tax forms adjusted for family size as the measure of well-being. One is the likely exclusion of various types of imputed income. An important source of imputed income for many families

of financial aid applicants is that resulting from owner-occupied housing. Net rental income--the difference between rent on comparable housing and necessary expenses of ownership--is not included in total income as defined in the Federal Income Tax. Other important examples of imputed income are the flow of services rendered by consumer durables and services rendered by housewives. Once again, the inclusion of such items in current income would certainly make income adjusted for family size more attractive as a measure of well-being. Of course, the inclusion of these items would seem to improve matters only to the extent that valid and reliable data could be collected on assets of all types. In addition, since the distinction between factor earnings and transfers seems of little relevance in determining family well-being, the income measure used should probably include all transfers including gifts. This is not the case with current income as reported on the Federal Income Tax.

Fluctuating incomes present a subtle problem in assessing the well-being of families of financial aid applicants to the extent that progression exists in the tax structure. Families with fluctuating incomes would be required to contribute more to postsecondary financing than families with stable incomes when total income throughout the period is identical. This is not, technically, an issue which relates specifically to the choice of an objective index of well-being. Rather, it pertains to the shape of the assumed well-being utility function and the nature of a resulting tax scheme. However, this problem can be attacked by constructing a measure of well-being which is an average over a specified time period--e.g., the years over which postsecondary attendance will occur or the life span of the parents of the applicant. However, to the extent that

averaging of income complicates data collection and verification procedures significantly, the disadvantage above becomes a significant one with regard to measuring well-being using only data on current income adjusted for family size.

Another point regarding the use of income adjusted for family size pertains to the use of income data which does not exclude the cost of acquiring income. The accretion concept of income is a net concept. As arbitrary as the decisions as to what to exclude must be, an attempt should be made to adjust data for such considerations.

Even if reported current income adjusted for family size corresponded perfectly with the accretion concept, many would still believe it to be an inadequate measure of family well-being. This position maintains that a system of taxation based upon such a measure would produce undesirable results since this measure ignores the stock of assets and/or the present value of expected future income. Consequently, it is argued, data on net assets, age, race, educational attainment, and sex should be considered.

The second framework to be discussed in this paper is one which requires the combining of current income and net assets into a measuring of well-being for each family. Before analyzing alternatives to do this, it should be pointed out that one of the most important reasons for preferring the use of current income alone is skepticism pertaining to the validity and reliability of self-reported asset information and the difficulty of verification. This discussion will assume for the time being at least that valid and reliable data on assets can be obtained from the families of aid applicants. The question then becomes one of how to handle such data.

In their 1968 article in the American Economic Review, Weisbrod and Hansen (8) discuss alternative methods for combining current income and net assets into a measure of well-being which they see as superior to measuring well-being using current income alone. Their basic approach is the conversion of net worth into an income flow (annuity value) which can be added to current income to produce a more comprehensive but operationally feasible measure of well-being. Hansen and Weisbrod's suggested measure of a family's economic position becomes:

$$Y_t^* = Y_t + NW_t \cdot A_n$$

where  $Y_t$  is current income,  $NW_t$  is current net worth, and  $A_n$  is the yearly return in dollars on a n-year annuity the present value of which is one dollar. Multiplication of  $NW_t$ , current net worth, by  $A_n$  produces the incremental current income which would result if the family's net worth were converted to an annuity. In doing this, Hansen and Weisbrod must distinguish conceptually between a theoretical method of summing current income and net worth and the problem of actually converting net worth into an annuity. Their method suggests neither that people do convert net worth to annuities or that they should. It simply suggests a new two-dimensional ranking device.

However, as Hansen and Weisbrod realize, the scheme above is not free of value judgment and arbitrary assumption. This point can best be made by investigating the derivation of  $A_n$  --the conversion factor. Two assumptions must be made before  $A_n$  may be evaluated for each family. First, an assumption concerning the discount rate must be made. Second, an assumption must be made concerning the time period for which the

annuity will be computed. Both of these assumptions will significantly effect the value of the measure of well-being for a given family, its ranking, and its relative well-being. Although consistent treatment seems to dictate the use of a common discount rate and time period for each family, the choice of specific rates and time periods is arbitrary.

It could be argued that because the choice of the discount rate involves a limited range of alternatives--e.g., 5% to 10%--this is not a significant problem especially for families whose income and net worth are close to the respective means. However, the choice of the time period is less constrained in that any time span from one year to infinity could be chosen. Suppose, for instance, that one believed that some assets should be liquidated or pledged as collateral against a loan to finance current postsecondary education expenditures. In this case, the current period can become the relevant time span requiring the simple addition of income and net worth, the sum of which would be adjusted for family size. Or, at the opposite extreme, the annuity could be computed to last forever. In this case, to the extent that the current income figure used corresponded to the accretion concept of income, well-being would be measured by current income alone as in the first framework discussed in this chapter. In the more probable case that current income did not include all accretions (e.g., imputed net rental income from owner-occupied housing), this would involve multiplying net worth by the assumed discount rate and adding the product to current income.

Between these two extremes, of course, exist many alternative time spans to consider. Those that seem most relevant are the alternatives that define the expected lifetime of the consuming unit in different ways.

For instance, the time period may be the average of the life expectancies of the father and mother or the period required to raise  $Y^*$  to some level. The important point is that each alternative may give rise to a significantly different perceived ranking and distribution of families according to well-being. An allowance for an estate at the time of expected death complicates matters still further.

It is interesting to investigate more closely one of these procedures for converting net worth to an annuity, namely, that which assumes annuitization over the expected lifetime of the consumer unit. For simplicity, define this period as the life expectancy of the mother. Table A.1 in the Appendix presents the value of  $A_n$  for various time spans. Table A.2 presents life expectancy figures. Using these, it is easy to construct the following table:

TABLE 2.1

NET WORTH CONVERSION RATES  
BY AGE OF WHITE MOTHERS

Age	Conversion Rate = $A_n$
40	.059
45	.062
50	.066
55	.072
60	.080

The table above illustrates that  $A_n$  increases as age increases. This is caused by the impact of a shorter time span on the value of an annuity which could be purchased with one dollar of net worth. If the data in the

table is used to construct measures of well-being for two families who differ only with regard to the age of the parents, it is clear that the "older" family will appear better off. Are they? It would seem to many that the family with the younger parents is better off. Indeed, this feeling might become stronger if one knew in addition that there was a strong positive relationship between age of parents and net assets among families of financial aid applicants. In summary, the treatment of families with older parents under the Hansen-Weisbrod scheme could appear as a significant disadvantage regardless of what time period was chosen for annuitization of net worth. In addition, this framework ignores, as does using current income alone, the present value of expected future income and its relationship to age, race, and educational attainment.

To the extent that periods preceding and following the period over which postsecondary education must be financed are deemed relevant to assessing well-being, both of the measures of well-being considered thus far are inadequate. Using income alone adjusted for family size obviously ignores past income history and, at best, assumes that current income is a good indicator of future income. Using income and net assets combined and adjusted for family size treats the past and the future in a rather peculiar fashion. The net asset position of a family is obviously a function of past income, consumption and investment expenditures. It might seem that including net assets helps to account for past income received. However, it also accounts for past expenditure patterns. Since families of identical size and age distribution may exhibit significantly different expenditure patterns over time even when income histories coincide, their net worth at any point time is likely to be different.

This, of course, will affect significantly the amount of financial aid received by dependents from each family when net assets are included in the well-being measure. With regard to future periods, the inclusion of net assets provides solely for the effect of the present level of such on future income. This in no way handles the problem of incorporating estimates of future income in the measure of well-being.

Before proceeding to describe a framework for incorporating expected future income in a measure of well-being, some remarks concerning the measurement of net worth are in order. If the data on assets are not rich enough to permit the construction of a good proxy for net worth, then use of income and net assets combined as the measure of well-being will discriminate among families not only according to total wealth but also according to the forms in which wealth is held. This is an important consideration since administrative convenience requires the collection of a manageable amount of asset data; while fairness requires that the data are valid and reliable indicators of the wealth position of the family. As has been mentioned previously, this trade-off can result in support of measuring well-being by current income alone adjusted for family size. It also can be used as an argument to support schemes which minimize the importance of assets by emphasizing current and expected future income. It is such a scheme to which this paper turns its attention.

The last framework for measuring the well-being of the families of aid applicants requires the computation of the present value of total resources and adjusting for family size. This approach has been recommended by Allan Cartter (6), and others. Whereas, the emphasis in the last framework was to convert net worth, a stock, to a flow which could be

added to current income, the present value approach requires estimating the present value of expected future earnings, a stock, and adding the estimate to net worth. The sum is then adjusted for family size. The crucial aspect of this process is the estimation of future expected income. Since it is not administratively feasible to estimate future income family by family, it is necessary to take an actuarial approach placing the family in a group of families each sharing important common characteristics. Conceptually, it is then necessary to assume that what applies to the group applies to each individual family assigned to that group.

Miller and Hornseth (3) have prepared for the Bureau of the Census estimates of the present value of lifetime earnings based on 1959 data from the 1960 Census. Estimates are presented which allow for alternative assumptions regarding annual productivity increases and discount rates. The estimates are derived from cross-sectional data on actual average current year earnings of males in 1959 by age, color, educational level, and occupation. The derivation of the estimates assumes that the relationship existing between age and average current earnings within each subgroup is a good guide as to how earnings behave as one's working life progresses. The average earnings for each age within each subgroup are reduced for mortality rates using 1964 data. At this point, this average annual earning data may be adjusted for expected productivity and price level changes.

For a particular subgroup the present value of expected future income through age 64 can be computed for each age level. This requires simply the discounting of the implicit income stream given by the values of average current income for the subgroup over the appropriate time span.

In addition, the resulting estimates of present value can be divided by average current income at each respective age to obtain ratios of present value to current income. Such ratios can then be used to convert current earnings to estimates of the present value of expected future income by simply multiplying current earnings (or a multi-year average of earnings) by the appropriate ratio for each family. Table A.3 in the Appendix presents these ratios for males with earnings in 1959--by age, race, and educational attainment. The present value approach would also require breakdowns by occupation and sex. However, data on occupation was not rich enough to provide useful estimates; while income data by sex did not exist as of this writing.

The significant differences in the ratios reported in Table A.3 seem to indicate the importance of considering the impact of age, color, and educational attainment upon expected future income and, hence, on perceived well-being. In general Table A.3 seems to suggest the following:

- (1) Age, not surprisingly, seems to have the greatest impact on the ratio of present value of future income to current income.
- (2) The impact of educational attainment upon expected future income varies inversely with age and is much more important for whites than nonwhites.
- (3) The ratios are significantly lower for nonwhites than whites for most age levels.

Before jumping to conclusions concerning the likely effects of employing estimates with the above characteristics, it is important to note that the impact of using the present value approach will be determined,

in part, also by the complex interrelationships among financial and demographic variables which exist in the actual aid applicant population. This is the reason for deferring the generation of hypotheses until Chapter Three, where distributions of well-being consistent with each framework are presented.

A major disadvantage of the present value approach appears to be its extraordinary dependence upon a data base rich enough to provide good estimates of expected future income, by age, color, educational attainment, sex, occupation, and other interesting categorizations. Since the two preceding approaches exhibit data problems also, it is not surprising that an approach which requires such estimates has even greater problems. However, it must be remembered that errors in the prediction of future income do not necessarily imply inequitable treatment of aid applicant families. The errors to be minimized are errors of horizontal and vertical equity. In this regard, the relevant consideration is the "appropriateness" of the present value approach relative to competing approaches.

As does the use of current income alone or current income and net assets combined, the present value approach to measuring the well-being of aid applicant families takes the past as given. Like the use of current income and net assets combined, there is the possibility that two families identical in all respects except for past consumption patterns will be treated differently because of different net worth positions. Unlike the previous framework, however, elderly parents are given an offsetting advantage since the present value of their expected future earnings will be small.

Lastly, a significant disadvantage of the present value approach is its complexity and sophistication. It is likely that a family, a financial aid administrator, even a congressman would find it hard to swallow the rather large dollar amounts parading as measures of family well-being. Even if these could be obscured in some way, the suggestion that a family is well off because of the income which will accrue to it through age 65 would still appear quite repugnant to many.

#### Implications for Family Consumption

Expenditures on postsecondary education, like expenditures on health care, have come to be considered investment in human capital. Although this framework seems appropriate when the recipient of such services is the purchasing agent, it is much less clear that it is useful in analyzing expenditures by parents on postsecondary educational services for their dependents. It seems to this writer that expenditures of this sort may fruitfully be considered consumption expenditures on the part of parents.

Although this study does not focus on the decision by the family unit regarding the amounts and types of educational services to purchase, the discussion up to this point has definite implications for the explanation of family expenditure patterns over its life cycle. It is important to note these briefly since an attractive alternative to distributing aid funds on the basis of perceived well-being is the efficient allocation of aid funds in order to impact in an optimal fashion the demand by the family for postsecondary educational services.

The framework of using current income alone adjusted for family size would seem consistent with the position that current family income is a

very important determinant of family consumption expenditures. Indeed if it could be demonstrated that the demand for postsecondary educational services were primarily a function of income over the appropriate years, the policy implication would be to use current income alone adjusted for family size (or some average of recent income data) as the measure of well-being upon which to distribute financial aid. This would be both equitable and efficient.

However, use of a measure of well-being consisting of current income and annuitized net worth would seem to imply that the family's net asset position was also an important determinant of consumption expenditures--and vice versa. A direct implication would seem to be that changes in transitory components of current income--e.g., income of mother, windfalls, etc.--would affect consumption expenditures far less than changes in permanent income even if the propensity to consume out of the "annuity" portion of well-being were greater than one. That is, such transitory income would effect only modest changes in consumption expenditures since the "annuity" value of transitory income rather than its absolute value is relevant.

Lastly, if the present value approach is taken, the implication is that of a consumption behavior very similar to a "life-cycle consumption function". Changes in the level of current income would have little effect on consumption expenditures unless the expected future income stream was simultaneously effected. This reduces the impact of current income upon consumption expenditures. However, unlike in a true life-cycle consumption framework, transitory income in the present value

approach presented in this paper seems to have a stronger impact on consumption expenditures since such income will change the current net worth position dollar for dollar.

In summary, it seems that the appropriateness of a given well-being measure might in part be determined by its success in "explaining" variations in family consumption.

#### Implications for Defining and Assessing the Progressivity of Taxes

Economists have long recognized that an important characteristic of a given tax structure is the resulting dollar burden stated as a function of dollar well-being. Since income has traditionally been used to measure well-being, economists have been interested in the behavior of the ratio of actual dollar burden to income as income increases. Terminology was thus created to describe three possibilities. A tax is referred to as progressive, regressive, or proportional depending on whether the ratio of tax paid to income increases, decreases, or remains constant as income increases. However, changing the dollar measure of well-being from income to some other measure seems to necessitate a change in the definition of progressivity, regressivity, or proportionality. Using the same framework above, it now seems clear that the appropriate ratio to consider is the ratio of tax paid in dollars to well-being in dollars, however measured.

Finally, when assessing the progressivity, regressivity, or proportionality of a tax based on income, or property, or some other variable, it seems appropriate to analyze the incidence of the tax in terms of what

is regarded as the best measure of well-being available. If competing measures of well-being exist, it would seem useful to assess progressivity, for instance, in light of each.

It is the purpose of Chapter Three to use financial and demographic data from 2,320 families of financial aid applicants to construct proxies for each measure of well-being considered in this chapter. The distributions of well-being are then presented and compared in order to generate a set of testable hypotheses. Finally, the effects of simple per capita income and wealth taxes upon the distributions are presented.

## CHAPTER III.

## THE DATA, COMPUTATIONS, AND RESULTS

The following chapter has four parts. First, a brief summary description of the data source and the computation of the various well-being proxies is presented. Second, the perceived distributions consistent with each well-being construct are depicted and compared. Third, the changing rankings of specific cohorts by age, color, and educational attainment are investigated. Fourth, a note is made concerning the assessment of the progressivity of income and wealth taxes.

The data source for this study at The American College Testing Program is an exceptionally rich file of financial and demographic information from families of financial aid applicants. This data was generated as part of another study, the purpose of which was to estimate demand curves for education by low-income families. Consequently, the drawing of the sample was not random from the population of financial aid applicants. Instead, there occurred deliberate oversampling of the nonwhite applicant population. This, of course, means that conclusions must be interpreted with caution. On the other hand, it will become clear that the major purpose of this study is not the estimation of population parameters. Rather, this study will use the data to demonstrate what happens to the perceived ranking of a particular group of families and to the distribution of well-being among those families when alternative measures of well-being are employed. This will result in a series of interesting hypotheses which can be tested using a data source

containing the necessary data elements and from which a random sample from all aid applicants can be drawn. Such a data base is not available at this time.

The data used in this study are drawn from 2,320 families in which at least one dependent had applied for financial aid. All data are self-reported and subject to the criticisms usually levied at such data. However, the validity and reliability of the data, although an extremely important consideration, is not at issue in this study. Rather, the issue is how such data is used to measure economic well-being. To investigate this, it is not necessary to assume the data is accurate, only that it serves as input to a need analysis model from which results a measure of well-being. A description of the families as a group in terms of the data elements used in the study is included in an Appendix.

Using this data, various measures of well-being are constructed and analyzed to assess their impact on the perceived distribution of well-being. These measures of well-being fall into the three main categories discussed in Chapter Two:

- (1) current income alone
- (2) current income and current net assets combined and
- (3) current and future income and current net assets combined.

Once these measures are constructed and evaluated for each family, the distribution of well-being is presented in two ways. First, a simple distribution by deciles is given. Second, the Lorenz distribution resulting from the use of each measure of well-being is presented. The distributions are then compared in terms of the degree of inequality

characterizing the distribution and the differential "treatment" of specific cohorts by age, educational attainment, and color, where such comparisons seem appropriate.

The first measure of well-being for each family is income per capita. Once again, the data used to construct the distribution of income per capita are self-reported data. Income is total family income reported on a financial aid application which is keyed to the Federal Income Tax 1040 form. The number used to adjust income is the number of persons in the family as reported on the same form. Assuming that such data are accurate, the distribution of family well-being as measured by income per capita is given by the table that follows.

TABLE 3.1  
DISTRIBUTION OF INCOME PER CAPITA

Decile	Income Per Capita	Share of Total Income Per Capita
1	702	2.3
2	1,000	4.3
3	1,267	5.7
4	1,538	7.1
5	1,789	8.3
6	2,091	9.8
7	2,414	11.2
8	2,836	13.1
9	3,504	15.7
10	11,033	22.5

Figure 3.1. Income Per Capita vs. Income.

The data in the Table can be used to construct a Lorenz Distribution which shows the cumulative portion of total well-being accounted for by successively higher percentages of families ranked from low to high in terms of the well-being measure. Figure 3.1 presents the Lorenz distributions of well-being as measured by income per capita. An approximate measure of the degree of inequality of such a distribution can be computed using the following formula given by Kravis (2):

$$R = \sum_{i=2}^k P_{i-1} Q_i - \sum_{i=2}^k P_i Q_{i-1}$$

where  $R$  is the approximate ratio of the area of concentration (OCB) to the area of maximum concentration (OAB),  $P$  is the cumulative percent of families,  $Q$  is the cumulative percent of well-being accounted for by these families, and  $i$  is one of  $k$  well-being classes ordered low to high. The value of  $R$  for the distribution of income per capita is .31. This measure of inequality is based on the assumption that equal absolute differences in well-being at different points in the distribution are of equal importance.

Also included in Figure 3.1 is the Lorenz distribution of well-being as measured by income uncorrected for family size. Because of the overall tendency for lower incomes to be associated with higher family sizes, this distribution is characterized by a lower discrete concentration ratio of .29. In addition, inspection of the rankings indicates that larger families are perceived as being better off when using income uncorrected for family size than when income per capita is used. For instance, when the measure of well-being is changed from income to income per capita the number of families of five members or more lying below the median changes from 550 to 795--a change of about 45%.

The results above lead us to our first testable hypotheses concerning the total financial aid applicant population. These hypotheses will alert researchers to important considerations in building or modifying need analysis models.

Hypothesis I. The Lorenz distribution of well-being as measured by income per capita will exhibit more inequality than the distribution of income alone.

Hypothesis Ia. Larger families will appear to be appreciably poorer when the measure of well-being is income per capita than when income uncorrected for family size is used.

It should be noted that the simple family size correction used in this study is not typical of methods usually employed to adjust for family size. There are many competing approaches to measuring well-being given different family sizes, as well as different age distributions of the family members. Each will in general give rise to a different distribution of well-being among the families under study. Also, to the extent that competing adjustment schemes incorporate differential treatment of families of equal size but different age distributions, the use of each may well imply a unique ranking of a specific group of families--even if all such adjustments are monotone increasing functions of family size.

The next set of well-being measures come under the heading of current income and assets combined. Alternative general approaches to achieving this have been discussed in Chapter Two. In this section each practical method used in constructing the well-being measures are explained briefly and, then, the distributions are presented. The simplest of these computations involve the addition of current income and net assets and division of the sum by family size. As was pointed out in previous chapters, this is consistent with an assumption of liquidation of net assets in the current period. When this is done for each family, the distribution which results is given in the table on the following page.

TABLE 3.2

DISTRIBUTION OF INCOME PER CAPITA + NET ASSETS PER CAPITA

Decile	$\frac{Y + NA}{N}$	Share of Total
1	1,130	1.7
2	1,769	3.3

8	6,127	13.0
9	8,167	16.1
10	35,528	27.0

Figure 3.2. Income Per Capita vs. Income Per Capita + Assets Per Capita

Once again the data in the table is used to construct the Lorenz distribution and compute the approximate measure of concentration. The concentration ratio for this distribution is .373 compared to .312 for the distribution of income per capita. This, along with Figure 3.2, demonstrates that the distribution of well-being as measured by income plus net assets (per capita) is more unequal than when the well-being measure is income per capita.

There are many factors which might contribute to the difference in inequality noted above. One of these is the degree of inequality in the distribution of net assets per capita. A concentration ratio of .544 shows the distribution of well-being as measured by net assets per capita to be more unequal than any of the other well-being measures used in this study. This distribution is presented below and the Lorenz distribution of net assets per capita appears in Figure 3.3. For purposes of comparison the distribution of income per capita is also presented again in Figure 3.3.

Once the assumption of full liquidation of net assets in the current period is relaxed, various techniques to combine income and net assets become available. The first considered here is the conversion of net assets to an incremental income flow by multiplying net assets by .05 and adding the result to income. As was stated previously, this is equivalent to computing the income stream in perpetuity which the net assets, if liquidated at full value, could purchase given a market interest rate of 5%. When this is done for each family, the distribution of well-being that results is that given in the table on the following page. Accompanying the distribution is the Lorenz diagram to which it gives rise. The

concentration ratio for this distribution is .317. Also included in Figure 3.4 for the sake of comparison is the Lorenz distribution of well-being as measured by income per capita plus net assets per capita. As was pointed out in Chapter Two, the two approaches which result in the distributions depicted in Figure 3.4 are opposite extremes in that the first implies an horizon of one period only, while the second implies an infinite horizon.

One last method suggested by Weisbrod and Hansen (8) of combining current income and net assets is considered here. This method takes advantage of data on the age, color and life expectancy of the main wage earner. In general, the essence of this technique of combining income and assets is that the annuity is computed to last over some definite time horizon between the current period and infinity. Alternative assumptions about the horizon are possible. For instance, in this study the time period is the number of years remaining until the expected death of the main wage earner. Based on the age, sex, and color of the main wage earner, a conversion factor is computed using the following formula given by Weisbrod and Hansen (8):

$$A_n = i[1 - (1 + i)^{-n}]^{-1}$$

where  $A_n$  is the income stream generated by \$1 worth of assets at interest rate  $i$  for a time period  $n$ . This formula has been discussed in Chapter Two and its derivation is presented in an Appendix. Once the value of  $A_n$  is computed for each family, it is used to convert net

assets to an income flow which is then added to current income. The sum is then deflated by family size. When this is done, the distribution of well-being is that given in the table and figure on the following page.

The reader will notice that this distribution is virtually the same as the distribution of well-being as measured by income plus .05 net assets. The concentration ratios are identical--.317.

The preceding analyses lead to the second set of testable hypotheses concerning the perceived distribution of well-being among families of financial aid applicants. In general, different methods of combining income and assets do not result in identical perceived distributions of well-being among families. In particular the following hypotheses seem appropriate.

Hypothesis II. The distribution of well-being as measured by income per capita plus net assets per capita will exhibit more inequality than the distribution of income alone uncorrected for family size.

Hypothesis IIa. The distribution of well-being as measured by net assets per capita will exhibit more inequality than the distribution of income alone, income per capita, or any of the combinations of income per capita and net assets per capita presented previously.

Hypothesis IIb. The distribution of well-being as measured by income per capita plus net assets per capita will exhibit more inequality than the distribution of income per capita plus some portion of net assets per capita.

9	3,742	15.5
10	11,137	22.3

Figure 3.5. Income Per Capita +  $A_n$  x Net Assets Per Capita.

Hypothesis IIc. The distribution of well-being as measured by income per capita plus .05 net assets per capita will exhibit the same degree of inequality as the distribution of income per capita plus  $A_n$  net assets per capita.

The last measure of well-being to be discussed in this chapter involves the combining of current and expected future earnings and net assets. Whereas in previous examples, net assets, a stock, were converted to a flow which could be added to income, this measure of well-being calls for adding to net assets, a stock, the present value of future expected income. This approach, in general, has been discussed in Chapter Two. The essence of this method, once again, is to compute the present value of future expected earnings for each main wage earner given his (her) age, color, and educational attainment using data from a Bureau of the Census paper by Miller and Hornseth (3). Then this amount is added to current income and the sum divided by family size. When this is done for each family, the distribution of well-being that results is that given in the table and figure on the following page. The concentration ratio is .359 for this distribution.

The results above lead to the following hypothesis.

Hypothesis III. The distribution of well-being as measured by the present value of resources per capita will exhibit more inequality than distributions of well-being which ignore future expected income.

The hypotheses generated thus far have dealt with the overall differences in the perceived distributions of well-being as measured by alternative indices. It is possible to look deeper into the distributions and

TABLE 3.6.

DISTRIBUTION OF THE PRESENT VALUE OF EXPECTED INCOME  
(PER CAPITA) PLUS NET ASSETS PER CAPITA

Figure 3.6. Present Value Per Capita + Net Assets Per Capita vs. Income Per Capita +  $A_n$  x Net Assets Per Capita.

generate hypotheses concerning the differential treatment of specific cohorts distribution by distribution. For the purposes of this study, families are grouped by age of main wage earner, educational attainment of main wage earner, and color. Then, the distribution of well-being of each cohort within the overall distribution is presented. This is done for the three distributions of well-being as measured by (1) income per capita, (2) income per capita plus  $A_n$  Net Assets per capita and (3) the present value of resources per capita.

The first cohort to be considered is that of all families with main wage earners over 60 years old. The percentages of such families falling into various deciles in the three distributions are compared in order to generate hypotheses concerning the impact of changes in the well-being measure upon families with older parents. Most families who apply for financial aid are characterized by heads in their late forties to mid-fifties. Consequently, isolating those with main wage earners 60 or over should result in some preliminary notions in this regard. The results are given in the table on the following page. The following hypotheses seem to be suggested.

Hypothesis IV. Families with older main wage earners will be perceived as poorer when present value per capita is used to measure well-being than when income per capita or income per capita plus  $A_n$  net assets per capita is used.

Hypothesis IVa. The inclusion or exclusion of net assets per capita will have no appreciable effect on the perceived well-being of families with older main wage earners.

TABLE 3.7.

PERCENT OF FAMILIES WITH MAIN WAGE EARNER OVER 60 YEARS  
OLD IN EACH DECILE OF THREE WELL-BEING DISTRIBUTIONS

Decile	$\frac{Y}{N}$	$\frac{Y}{N} + A \frac{NA}{nN}$	$\frac{\text{Present Value}}{N}$
1	9.2%	9.2%	41.4%
2	10.5	7.2	27.0
3	9.9	9.9	15.1
4	9.9	9.9	7.2
5	10.5	8.6	4.6
6	5.9	7.9	2.0

9	7.9	10.5	0.0
10	13.8	13.8	0.7

The second cohort to be considered here is that of nonwhite families. The following table presents data on the perception of well-being among nonwhite families within the same three distributions.

The results in Table 3.8 seem to suggest the following hypothesis.

Hypothesis V. The perceived distribution of well-being among nonwhite families will not change appreciably when net assets per capita and/or expected future income is included with income per capita in the well-being measure.

generate hypotheses concerning the differential treatment of specific cohorts distribution by distribution. For the purposes of this study, families are grouped by age of main wage earner, educational attainment of main wage earner, and color. Then, the distribution of well-being of each cohort within the overall distribution is presented. This is done for the three distributions of well-being as measured by (1) income per capita, (2) income per capita plus  $A_n$  Net Assets per capita and (3) the present value of resources per capita.

The first cohort to be considered is that of all families with main wage earners over 60 years old. The percentages of such families falling into various deciles in the three distributions are compared in order to generate hypotheses concerning the impact of changes in the well-being measure upon families with older parents. Most families who apply for financial aid are characterized by heads in their late forties to mid-fifties. Consequently, isolating those with main wage earners 60 or over should result in some preliminary notions in this regard. The results are given in the table on the following page. The following hypotheses seem to be suggested.

Hypothesis IV. Families with older main wage earners will be perceived as poorer when present value per capita is used to measure well-being than when income per capita or income per capita plus  $A_n$  net assets per capita is used.

Hypothesis IVa. The inclusion or exclusion of net assets per capita will have no appreciable effect on the perceived well-being of families with older main wage earners.

TABLE 3.8.

PERCENT OF NONWHITE FAMILIES IN EACH DECILE  
OF THREE WELL-BEING DISTRIBUTIONS

Decile	$\frac{Y}{N}$	$\frac{Y}{N} + A \frac{NA}{n N}$	<u>Present Value</u> N
1	19.5%	22.6%	21.7%
2	17.3	15.8	16.7
3	11.7	12.4	11.5
4	12.4	12.1	12.1
5	9.2	8.3	10.5
6	7.1	7.0	6.7
7	5.9	6.4	6.8
8	5.8	5.3	5.6
9	6.4	5.9	5.9
10	5.0	4.2	4.4

The last cohort to be investigated is that of families whose main wage earner has at least a college education. The distribution of such families within the three overall distributions are presented in Table 3.9.

The results in Table 3.9 seem to suggest the following hypothesis.

Hypothesis VI. The distribution of well-being among families with main wage earners with 16 or more years of education will not change appreciably when net assets per capita and/or expected future income is included with income per capita in the well-being measure.

TABLE 3.9.

PERCENT OF FAMILIES WITH MAIN WAGE EARNER WITH  
16 OR MORE YEARS OF SCHOOLING IN EACH DECILE  
OF THREE WELL-BEING DISTRIBUTIONS

Decile	$\frac{Y}{N}$	$\frac{Y}{N} + A \frac{NA}{nN}$	$\frac{\text{Present Value}}{N}$
1	1.8%	1.8%	2.8%
2	4.0	3.7	3.7
3	7.4	8.6	6.8
4	8.6	5.8	8.3
5	9.2	10.5	7.7
6	12.3	12.3	9.8
7	9.8	9.8	11.4
8	12.9	14.8	16.6
9	16.3	15.1	12.9
10	16.9	17.5	19.7

The last section of this chapter deals with assessing the progressivity, regressivity, or proportionality of income and asset taxes. It has been suggested in Chapter Two that the use of a measure of well-being other than current income requires a change in the way one defines progressivity. That is, for instance, if current income per capita plus some portion of net assets per capita is chosen as the measure of well-being, a tax is progressive if and only if the percentage of well-being

sacrificed in taxes increases as well-being increases. The following analysis pertains to the overall effect of a per capita income tax and a per capita net asset tax on well-being defined in alternative ways.

A 10% tax on current income per capita will leave unchanged the distribution of well-being as measured by income per capita. However, it will change the distribution of well-being as measured by indices which include net assets and/or future expected income. Such is also the case when considering the progressivity of a per capita net asset tax. The tables on the following page present the results of levying the specified tax on the distribution of well-being measured in alternative ways.

The table shows that a 10% per capita income tax is not a proportional tax when the measure of well-being is either income per capita plus  $A_n$  net assets per capita or present value per capita. For both measures of well-being, there are ranges where the percent of well-being paid in tax increases. Although an overall pattern is difficult to discern with respect to the 10% per capita income tax, this is not true for the 5% per capita net asset tax which exhibits a regressive character for the well-being measures under study. The table suggests that the inclusion of net assets per capita diminishes the regressivity of the latter tax--as does the inclusion of expected future income. It should also be noted that the differences in the absolute sizes of the percents in the table are to be expected since different dollar values are involved with each measure of well-being.

## CHAPTER IV.

## SUMMARY AND CONCLUDING REMARKS

The equitable distribution of aid funds is viewed in this paper as a problem in taxation according to ability to pay or well-being. This approach is emphasized because it is fruitful to consider the various financial need analysis models as systems of taxation which result in the parents' expected contribution to the postsecondary education of their dependents. However, this study deals with only the first step in the development of an equitable tax system--i.e., the construction and evaluation of an objective index of ability to pay or well-being. The definition of equal sacrifice and specification of a well-being utility function are not discussed. It is the writer's opinion that the choice of measure of well-being must precede other considerations in developing an equitable system of taxation. Accordingly, a simple two-step model is suggested for evaluating alternative measures of well-being. The first step is a comparison of the theoretical implications of competing measures. The second step is a comparison of the implications of each measure for the perceived distribution of well-being among aid applicant families. Such a comparison serves an important function. It provides an insight into the possible impact of various theoretical propositions upon the ranking of a group of families among whom exist complex financial and demographic interrelationships thereby expediting the generation of meaningful hypotheses. Indeed, in this regard, this study and future investigations of the consequences of using a given measure of

well-being can help in bypassing some of the difficulties inherent in the construction of a well-being utility function and facilitate the specification of an equitable tax system.

#### Limitations of the Analysis

This study is necessarily limited in scope. As was pointed out in Chapter Two, only the first step in the construction of an equitable system to distribute financial aid is considered--the construction and evaluation of an objective measure of family well-being. The choice and evaluation of such a measure is viewed as a problem in social policy--the minimization of inequity subject to administrative constraints. No attempt is made to specify the demand for postsecondary educational services on the part of the families of aid applicants. It seems that future research might be directed at explaining consumption patterns of these families especially over the time span of postsecondary attendance. If consumption patterns can be explained most adequately in terms of one of the competing frameworks for measuring well-being, it would seem best to use that framework for distributing scarce aid funds.

Also this study is confined to the generation of testable hypothesis rather than the actual testing of hypotheses. This is necessary because an adequate data base does not exist to allow for proper sampling of the aid applicant population. In particular, such items as educational attainment of parents and race are not routinely collected by present need analysis systems. However, if such a data base becomes available the hypotheses generated in Chapter Three will provide a framework for analyzing the perceived well-being of aid applicant families. Until such

time, the data presented in Chapter Three should serve as warning to individuals responsible for revising present need analysis procedures. The form of each hypothesis is meant to alert researchers to the result expected by this writer. For instance, Hypothesis V suggests that the perceived distribution of well-being among nonwhite families will not change significantly when expected future income is included in the well-being measure. This is startling since the present value approach is supposed to sensitize the measure of well-being to the effects of color on expected future income.

It is the conclusion of this study that received economic theory can be useful in analyzing the implications of measuring well-being in alternative ways. However, a theoretical investigation raises as many questions as it answers. The choice of a measure of well-being involves many arbitrary assumptions and value judgments. Received theory is valuable primarily in identifying the truly normative aspects of models used to assess well-being and in pinpointing the consequences of assumptions and value judgments.

## ACKNOWLEDGEMENTS

I would like to express my gratitude to the American College Testing Program for their support of this study. In particular, I thank Dr. James Maxey for his help in all phases of the study and to Teresa Meyer for extensive editing of the data and typing of the manuscript.

I would like to extend special thanks to my major professor, Dr. Dennis R. Starleaf, who through his excellent teaching and patient counseling has been the major influence on my professional development.

Derivation of  $A_n$ 

The income stream  $A_n$  generated by \$1 worth of assets at a given interest rate  $i$  must satisfy the following equation:

$$\$1 = \frac{A_n}{(1+i)} + \frac{A_n}{(1+i)^2} + \dots + \frac{A_n}{(1+i)^n} .$$

Let  $Z = (1+i)^{-1}$ , then

$$\$1 = A_n [Z + Z^2 + \dots + Z^n] .$$

Adding and subtracting  $A_n$  and rearranging terms,

$$\$1 = A_n [1 + Z + Z^2 + \dots + Z^{n-1}] - A_n + A_n Z^n .$$

Replacing the finite geometric series in the parentheses with its solution,

$$\$1 = A_n \left[ \frac{1 - Z^n}{1 - Z} \right] - A_n + A_n Z^n .$$

Solving for  $A_n$ ,

$$A_n = \frac{1}{\left[ \frac{1 - Z^n}{1 - Z} \right] - 1 + Z^n} .$$

Simplifying,

$$A_n = \frac{1 - Z}{Z(1 - Z^n)}$$

Substituting  $(1+i)^{-1}$  for  $Z$  yields the final result:

$$A_n = i[1 - (1+i)^{-n}]^{-1} .$$

The purpose of this section is to describe the sample of students responding to ACT's College Investment Decision questionnaire. Two of ACT's Research Service instruments--the Class Profile Report and the Profile of Financial Aid Applicants--were used to organize the data and provide comparisons to national norms in some cases. These data fall into six main categories: (1) general demographic information, (2) academic ability, (3) educational aspirations, (4) student personnel needs, (5) college attractions, and (6) family financial background. The following tables provide a brief summary of sample student characteristics in each of these areas emphasizing comparison to national norms, when such are available.

# I. GENERAL DEMOGRAPHIC INFORMATION

\*Small Discrepancies May Occur Due to Rounding.

## II. ACADEMIC ABILITY

## A. Mean Scores on ACT Assessment

	<u>English</u>	<u>Math</u>	<u>Social Studies</u>	<u>Natural Science</u>	<u>Composite</u>
Men	18.1	22.4	20.7	22.6	21.1
Women	19.7	19.5	19.5	20.7	20.0
Total	19.1	20.6	20.0	21.4	20.4
Norm	18.7	20.2	19.9	21.0	20.1

## B. Percent of Students in Selected Composite Score Intervals

	<u>1-15</u>	<u>16-20</u>	<u>21-25</u>	<u>26-36</u>
Sample	21	25	32	22
Norm	20	32	33	15

## C. Mean High School Grade Point Covering Areas Above

	<u>Men</u>	<u>Women</u>	<u>Total</u>
Sample	2.89	3.09	3.01
Norm	-	-	2.68

## D. Percent of Students in Selected Grade Point Intervals

	<u>0-1.4</u>	<u>1.5-2.4</u>	<u>2.5-3.4</u>	<u>3.5-4.0</u>
Sample	1	18	49	32
Norm	2	33	48	17

## E. Percent of Students Graduating in High School Classes of Different Sizes

	<u>1-24</u>	<u>25-99</u>	<u>100-399</u>	<u>400-up</u>
Sample	5	27	40	27
Norm	4	19	45	33

## F. Percent of Students Participating in Honors/Advanced Program in High School - 49%

## III. EDUCATIONAL ASPIRATIONS

## A. Percent of Students Proposing Various Educational Majors

	<u>Sample</u>	<u>Norm</u>
Educational	20	18
Soc./Religious	13	10
Bus./Pol.	17	18
Scientific	8	7
Agric./For.	2	3
Health	12	9
Arts/Human	12	12
Engineering	6	8
Trade/Ind./Tech.	2	3
Undecided	8	11

## B. Percent of Students Seeking Various Degrees

	<u>Sample</u>	<u>Norm</u>
Voc./Tech.	1	2
Two Yr. College	8	12
B.A., B.S., B.D.	47	47
M.A., M.S.	26	23
Ph.D., Ed.D.	14	12
Other	5	5

## IV. STUDENT PERSONNEL NEEDS

## A. Percent of Students Planning to Use Housing of Various Types

	<u>Sample</u>	<u>Norm</u>
College Housing	69	55
Off Campus	7	9
At Home/Relative	24	36

## B. Percent of Students Planning to Bring Car - 33% (Norm - 47%)

## C. Percent of Students Expressing Various Special Educational Needs (Reading Skills, etc.) - All Less than Average

## D. Percent of Students Desiring to Participate in Various Honors/Advanced Programs and Extracurricular Activities - All Greater than Average

## E. Percent of Students Expecting to be Full Time - 96% (Norm - 93%)

## F. Percent of Students Out of High School One Year or More - 5% (Norm - 8%)

## V. COLLEGE ATTRACTIONS

## A. Percent of Students Indicating Various Items as Major Influences in Selecting College Show Sample Students Placing More Weight than Average on Intellectual Reputation and Financial Considerations

## B. Percent of Students Indicating Financial Considerations as Most Important - 19% (Norm - 11%)

## VI. FAMILY FINANCIAL PROFILE

The average financial aid applicant in the sample comes from a family whose average income is \$8,500; and has 2 brothers and sisters, 0 of whom are also in college.

The median incomes for different family members are as follows: the father earns \$6,700; the mother earns \$0; the single dependent applicant earns \$550; and the combined income of married dependent

applicants is \$1,250. The mean income for single independent students is \$2,792, and the combined income of married independent students is \$5,885.

Although the father of the typical dependent applicant is salaried or a wage earner (84%), 11% are farm owners and 5% are business owners. The average age of the main family earner is 49, the applicant's parents has net assets valued at \$7,750, and if they own a home, it is valued at \$12,804.

The average commuter need is \$839 and the average resident need is \$1,281. The typical applicant is single and dependent on parental support, 2.7% of the applicants are married and 5.0% are independent.
